Abstract

This article describes a robot walker based on a new single degree-of-freedom six-bar leg mechanism that provides rectilinear, non-rotating, movement of the foot. The walker is statically stable and requires only two actuators, one for each side, to provide effective walking movement on a flat surface. We use Curvature Theory to design a four-bar linkage with a flat-sided coupler curve and then adds a translating link so that walker foot follows this coupler curve in rectilinear movement. A prototype walker was constructed that weighs 1.6 kg, is 180 mm tall, and travels at 162 mm/s. This is an innovative legged robot that has a simple reliable design.

1. Introduction

This paper presents the design and control of a new four-legged robot walker that is driven by two actuators to provide steerable movement on a horizontal surface. Each side of the walker has a leg system formed by two six-bar legs connected to a single DC motor-driven input crank. The leg systems on each of two sides are controlled independently to determine the forward, reverse and turning operation of the walker. See Fig. 1 which shows our Steerable Two Actuator Robot (STAR) walker.

The kinematic synthesis theory that we used to design leg mechanisms that have rectilinear, non-rotating, foot trajectories is presented in detail. This technique uses the differential geometry of point trajectories in a planar moving body to design a linkage with a flat-sided coupler curve. The resulting leg mechanism has a foot that moves in a rectilinear fashion, which means all points in the foot trace the flat-sided trajectory while in contact with the ground.

Our walker uses legs that have one degree-of-freedom (DoF), in contrast to the three degree-of-freedom legs used in most walkers, see Hirose [1], Song and Waldron [2]. Also, see Buchanan et al. [3] and Yu et al. [4]. Our design uses two actuators for movement rather than as many as 12 actuators for a four-legged walker, which significantly reduces the weight and simplifies control.

2. Literature review

There are several walking robots that use only two actuators. Collins et al. [5] show that a bipedal robot can walk effectively with two actuators when combined with passive dynamics. Hoover et al. [6] present an insect-sized hexapod robot that is driven by two actuators, one for forward movement and one for turning. Hoover et al. [7] present a larger and faster hexapod also driven by two actuators. Recently, Islam et al. [8] show that a small bipedal passive dynamic walker with an extension actuator in each leg can provide steerable walking movement. In contrast, our walker is statically stable as it walks because of the design of its leg mechanisms.

The leg mechanism for our walker is designed to guide the foot so that it translates without rotating, which means with two feet on the ground the walker is statically stable. The technique we apply to

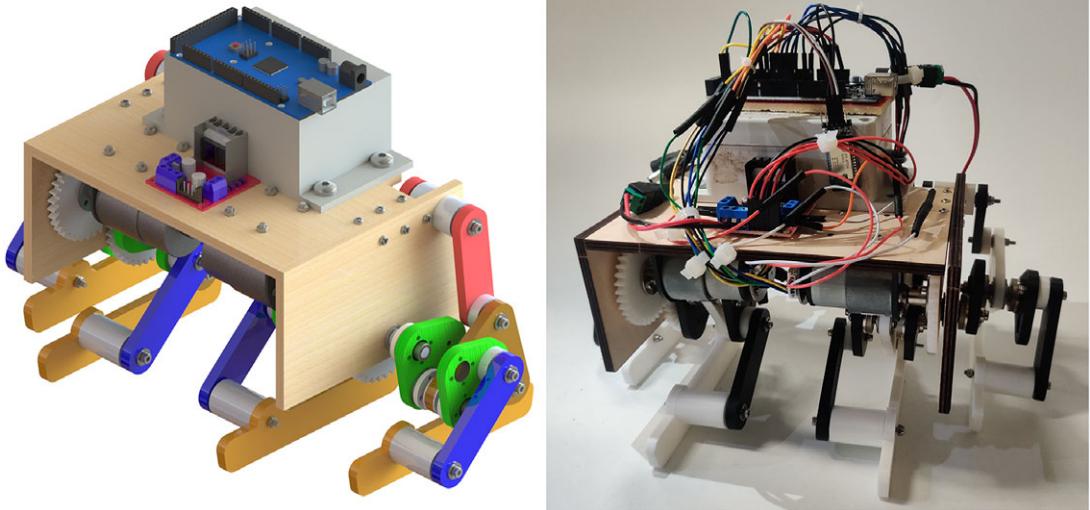

Figure 1. The solid model and the prototype of our STAR (Steerable Two Actuator Robot) walker.

design this mechanism adapts kinematic synthesis of planar curves to the specific demands of walking machines. Cera and Penestri [9] describe the mathematical foundation for this synthesis process, which we present below using “instantaneous invariants” – also see Cera and Pennestri [10]. Instantaneous invariants were introduced by Veldkamp [11] to simplify the study of the curvature of planar point trajectories. For recent discussions of instantaneous invariants, see Roth [12] and Figliolini and Lanni [13].

The design of specialized robot leg mechanisms can be found as early as Shigley [14], and Funabashi [15, 16]. Shieh et al. [17] present a variety of six-bar and eight-bar leg mechanisms combining a four-bar linkage with skew-pantograph and pantograph linkages. Liang et al. [18] and Haldane et al. [19] have demonstrated the performance advantages of specialized leg mechanisms. Recent work on minimally actuated robot walkers with one or two actuators per leg and the use of a tail to balance the walker is presented by Saab et al. [20] and Liu and Ben-Tzvi [21]. Our leg mechanisms differ from these examples in that our robot has two six-bar legs on one side that are driven by a single motor and maintain static stability by using translating feet.

We compare our walker to six similarly sized walkers with regard to weight, speed, and degrees of freedom. In particular, we consider the omni-directional quadruped by Gu et al. [22], who explore the potential of over-constrained linkages in leg design; the SQuRo quadruped robot by Shi et al. [23], which is a small-sized adaptable walker; the Cheetah-cub-S walker by Weinmeister et al. [24], which features integrated spine-like structures; the NeRmo walker by Lucas et al. [25], which is a modular bio-mimetic robot inspired by a mouse; and the WR-1 and WR-2 animaroid walkers by Ishii et al. [26, 27], which are designed to study social interaction with rodents. This comparison shows that the STAR walker’s emphasis on minimal actuation yields a generally stronger and faster walker.

3. Leg mechanism design

The kinematic synthesis of our leg mechanism proceeds in two steps. First, a four-bar linkage with a flat-sided coupler curve is designed using the differential properties of the trajectories generated by a planar moving body. This technique is known as “instantaneous position synthesis,” but for our purposes is better described as *differential kinematic synthesis*. The second step is to modify resulting linkage by adding two links in order to provide a foot that translates, without rotating, so that every point follows the same trajectory. A graphical version of this design procedure is presented in McCarthy [28].

In what follows, we present an analytical formulation of curvature theory which is the foundation for differential kinematic synthesis using instantaneous invariants. This formulation is not readily available in the current literature.

3.1. Curvature theory

The coupler of a four-bar linkage traces planar point trajectories that can be studied using *Differential Geometry*. See do Carmo [29] and Tapp [30]. A fundamental result is that a planar curve is characterized by its *curvature* at every point along the curve. In kinematics of planar movement, curvature theory studies the curvature properties of all point trajectories in the body. Remarkably, information about these properties can identify a four-bar linkage and a coupler point with a flat-sided coupler curve, which are well-adapted for use in leg mechanisms.

3.1.1 Planar motion of a rigid body

Consider the rigid movement of a planar body, M , relative to a fixed body F , defined by the rotation angle ϕ measured between the x axes of M and F and the translation vector $\mathbf{d} = (a, b)$ measured from the origin of F to the origin of M . If the parameters ϕ , a and b vary with time, then planar motion is the parameterized transformation of coordinates \mathbf{p} of a point in M to its trajectory $\mathbf{P}(t)$ in F , given by,

$$\mathbf{P}(t) = \begin{Bmatrix} X(t) \\ Y(t) \\ 1 \end{Bmatrix} = \begin{bmatrix} \cos \phi(t) & -\sin \phi(t) & a(t) \\ \sin \phi(t) & \cos \phi(t) & b(t) \\ 0 & 0 & 1 \end{bmatrix} \begin{Bmatrix} x \\ y \\ 1 \end{Bmatrix} = \mathbf{D}(t)\mathbf{p}. \tag{1}$$

The 3×3 homogeneous transform \mathbf{D} is similar to the 4×4 homogeneous transforms used in Robotics, McCarthy [31]. We use this 3×3 matrix to simplify our derivations, however, we will drop the homogeneous coordinate 1 in $\mathbf{P}(t)$ and \mathbf{p} when it is convenient.

The focus of curvature theory is on the geometric properties of point trajectories, therefore, rather than using time t as a parameter, we use the rotation angle ϕ of the moving body. We reparameterize the components of the translation vector so we have $a(\phi)$ and $b(\phi)$. Thus, the motion of a planar rigid body is given by the coordinate transformation,

$$\mathbf{P}(\phi) = \begin{Bmatrix} X(\phi) \\ Y(\phi) \\ 1 \end{Bmatrix} = \begin{bmatrix} \cos \phi & -\sin \phi & a(\phi) \\ \sin \phi & \cos \phi & b(\phi) \\ 0 & 0 & 1 \end{bmatrix} \begin{Bmatrix} x \\ y \\ 1 \end{Bmatrix} = \mathbf{D}(\phi)\mathbf{p}. \tag{2}$$

This equation defines the trajectory $\mathbf{P}(\phi)$ traced in a fixed frame F by the point \mathbf{p} in the moving frame M . This can be viewed as a map of all the points of M to trajectories in F .

In order to study the differential properties of a trajectory $\mathbf{P}(\phi)$, we introduce notation for the derivatives of \mathbf{P} at the instant $\phi = 0$,

$$\mathbf{P}(0) = \mathbf{P}_0, \quad \frac{d\mathbf{P}}{d\phi}(0) = \mathbf{P}_1, \quad \frac{d^2\mathbf{P}}{d\phi^2}(0) = \mathbf{P}_2, \quad \frac{d^3\mathbf{P}}{d\phi^3}(0) = \mathbf{P}_3, \quad \dots \tag{3}$$

We use this notation in the definition of the *instantaneous invariants* of a planar motion.

3.1.2 Instantaneous invariants

In every position of the moving body M , there is a point \mathbf{V} , known as the *velocity pole* or the *instant center of rotation*, that has zero velocity relative to the fixed body F . The set of poles for the movement of M relative to F is called a *centrode*. For a specific position of the moving body, we choose the pole \mathbf{V} as the origin of coordinates for both the fixed frame F and moving frame M , and the tangent to the centrode as the x -axis for what is known as the *canonical coordinate system*.

Using the canonical coordinate system, we obtain the Taylor series expansion of the motion near the reference position $\phi = 0$ in the form,

$$\mathbf{D}(\phi) = I + \mathbf{D}_1\phi + \mathbf{D}_2\frac{\phi^2}{2} + \mathbf{D}_3\frac{\phi^3}{6} + \dots \quad (4)$$

where the matrices \mathbf{D}_i are calculated to be,

$$\mathbf{D}_1 = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{D}_2 = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & b_2 \\ 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{D}_3 = \begin{bmatrix} 0 & 1 & a_3 \\ -1 & 0 & b_3 \\ 0 & 0 & 0 \end{bmatrix}. \quad (5)$$

This shows that every planar motion is defined by the set of constants b_2, a_3 and b_3 to the third order, which are known as *instantaneous invariants*, Bottema and Roth [32].

The trajectory $\mathbf{P}(\phi)$ in F traced by a point $\mathbf{p} = (x, y)$ in the frame M following the motion $\mathbf{D}(\phi)$ defined by (4) is given by,

$$\mathbf{P}(\phi) = \mathbf{p} + \mathbf{P}_1\phi + \mathbf{P}_2\frac{\phi^2}{2} + \mathbf{P}_3\frac{\phi^3}{6} + \dots \quad (6)$$

where

$$\mathbf{P}_1 = \begin{Bmatrix} -y \\ x \end{Bmatrix}, \quad \mathbf{P}_2 = \begin{Bmatrix} -x \\ -y + b_2 \end{Bmatrix}, \quad \mathbf{P}_3 = \begin{Bmatrix} y + a_3 \\ -x + b_3 \end{Bmatrix}. \quad (7)$$

This equation can be viewed as defining all of the trajectories $\mathbf{P}(\phi)$ associated with all points $\mathbf{p} = (x, y)$ in the moving plane M .

We study the differential properties of all of the trajectories in the moving body in order to obtain the inflection circle, the Euler-Savary equation, and the cubic of stationary curvature.

3.1.3 Differential properties

The local properties of each trajectory in the moving body are studied using the unit tangent \mathbf{T} and unit normal \mathbf{N} vectors described in do Carmo [29] and Tapp [30]. Using (6), we can compute these vectors to be,

$$\mathbf{T} = \frac{\mathbf{P}'}{|\mathbf{P}'|} = \frac{1}{(x^2 + y^2)^{1/2}} \begin{Bmatrix} -y \\ x \end{Bmatrix}, \quad \text{and} \quad \mathbf{N} = \mathbf{T}^\perp = \frac{1}{(x^2 + y^2)^{1/2}} \begin{Bmatrix} -x \\ -y \end{Bmatrix}, \quad (8)$$

where \mathbf{T}^\perp is \mathbf{T} rotated $\pi/2$ counterclockwise. The prime in these equations is the traditional notation for derivatives with respect to the curve parameter, in our case ϕ .

The curvature κ of a trajectory $\mathbf{P}(\phi)$ is calculated using the formula from differential geometry,

$$\kappa = \frac{\mathbf{P}' \times \mathbf{P}''}{(\mathbf{P}' \cdot \mathbf{P}')^{3/2}} = \frac{x^2 + y^2 - b_2y}{(x^2 + y^2)^{3/2}}. \quad (9)$$

This equation shows that the set of points $\mathbf{p} = (x, y)$ in the moving body with trajectories $\mathbf{P}(\phi)$ having zero curvature, that is with $\kappa = 0$ at the instant $\phi = 0$, satisfy the equation,

$$\mathcal{I} : x^2 + y^2 - b_2y = 0, \quad (10)$$

which defines a circle, known as the *inflection circle*, Fig. 2.

The center of curvature \mathbf{C}_p for each trajectory $\mathbf{P}(\phi)$ is defined by the formula,

$$\mathbf{C}_p = \mathbf{p} + \frac{1}{\kappa}\mathbf{N}, \quad (11)$$

where $\rho = 1/\kappa$ is the *radius of curvature*. The center of curvature defines a circle with radius ρ that fits the trajectory to the second order. Substitute (8) and (9) into the above equation to obtain,

$$\mathbf{C}_p = \begin{Bmatrix} x \\ y \end{Bmatrix} + \frac{x^2 + y^2}{x^2 + y^2 - b_2y} \begin{Bmatrix} -x \\ -y \end{Bmatrix}. \quad (12)$$

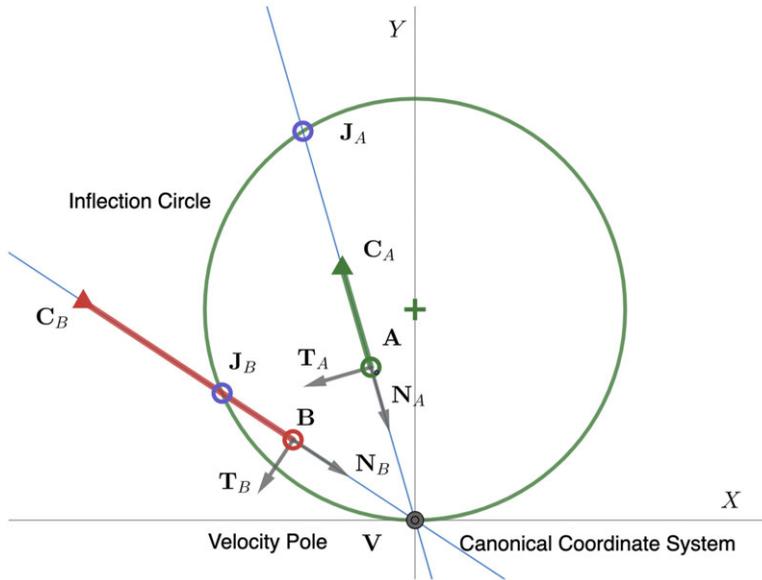

Figure 2. The canonical coordinate system simplifies the equations that define tangent \mathbf{T}_A and normal \mathbf{N}_A vectors for a trajectory \mathbf{A} , as well as for its the center of curvature \mathbf{C}_A .

This definition of the center of curvature (12) takes a simpler form using polar coordinates in the canonical frame and yields the Euler-Savary equation, Uicker et al. [33].

3.1.4 Euler-Savary equation

Consider a ray through a point \mathbf{p} and the origin \mathbf{V} of the canonical coordinate system, and introduce polar coordinates, so $\mathbf{p} = (R \cos \theta, R \sin \theta)$. Recall that \mathbf{V} is the instant center of rotation for the moving body, which means that the tangent vector \mathbf{T} of the trajectory $\mathbf{P}(\phi)$ is perpendicular to this ray, and the normal vector \mathbf{N} is along this ray. Using these polar coordinates, the curvature κ is given by,

$$\kappa = \frac{R - b_2 \sin \theta}{R^2}. \tag{13}$$

The center of curvature can be computed to be,

$$\mathbf{C}_p = R \begin{Bmatrix} \cos \theta \\ \sin \theta \end{Bmatrix} - \frac{R^2}{R - b_2 \sin \theta} \begin{Bmatrix} \cos \theta \\ \sin \theta \end{Bmatrix}, \tag{14}$$

where it becomes clear that \mathbf{C}_p lies on the ray through \mathbf{p} at the angle θ and at the distance $R_c = R - \rho$ from the origin.

This ray intersects the inflection circle at the distance R_l given by

$$R_l = b_2 \sin \theta. \tag{15}$$

Substitute R_l into the formula for the radius of curvature $\rho = R - R_c$ to obtain,

$$R - R_c = \frac{R^2}{R - R_l} \quad \text{or} \quad R^2 = (R - R_c)(R - R_l), \tag{16}$$

which is known as the *Euler-Savary equation*, Uicker et al. [33].

The Euler-Savary equation provides a formula for the location of the center of curvature \mathbf{C}_A associated with the trajectory of a point \mathbf{A} using the radial distances from the velocity pole to the point \mathbf{A} and to the point of intersection \mathbf{J}_A of this ray with the inflection circle. Repeat this calculation to obtain the center

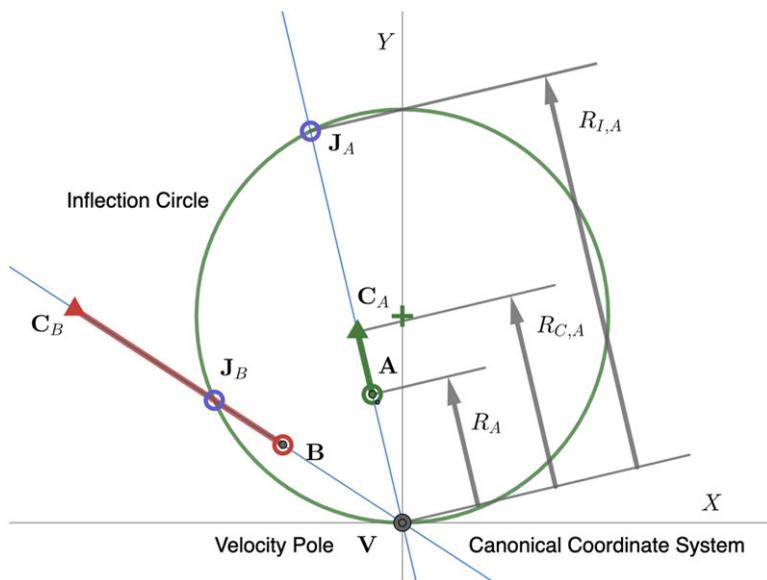

Figure 3. The Euler-Savary equation relates the radial distance to the center of curvature R_{C_A} to the radial distance R_A and the radial distance $R_{I,A}$ to the intersection with the inflection circle.

of curvature C_B for a second point B in order to obtain the four-bar linkage C_AABC_B that has a coupler motion that matches the moving plane to the second order, Fig. 3.

3.1.5 Ball's point

We now consider the rate of change of the curvature of trajectories in the moving plane. Compute the derivative of the formula for curvature κ in (9) to obtain,

$$\frac{d\kappa}{d\phi} = \frac{(\mathbf{P}' \times \mathbf{P}''')(\mathbf{P}' \cdot \mathbf{P}') - 3(\mathbf{P}' \times \mathbf{P}'')(\mathbf{P}' \cdot \mathbf{P}'')}{(\mathbf{P}' \cdot \mathbf{P}')^{5/2}} \tag{17}$$

Substitute (6) into this equation to obtain a formula for the rate of change of curvature in the reference position $\phi = 0$ for every point $\mathbf{p} = (x, y)$ in the moving plane,

$$\kappa_1 = \frac{-(x^2 + y^2)(a_3x + b_3y) - 3b_2x(x^2 + y^2 - b_2y)}{(x^2 + y^2)^{5/2}} \tag{18}$$

The points with trajectories having a zero rate of change of curvature, that is with $\kappa_1 = 0$, maintain the same curvature to the third order. These trajectories are said to have stationary curvature, and are defined by points that lie on the cubic curve,

$$C:(x^2 + y^2)(a_3x + b_3y) + 3b_2x(x^2 + y^2 - b_2y) = 0, \tag{19}$$

known as the *cubic of stationary curvature*.

The intersection of the cubic of stationary curvature and the inflection circle defines a point in the moving body that follows a straight line to the third order known as *Ball's point*, Fig. 4.

3.1.6 Differential kinematic synthesis

Kinematic synthesis of a four-bar linkage for movement of a body M near a reference position seeks point trajectories A and B that lie on circles to the third order. These points lie on the *cubic of stationary curvature* and are used as the moving pivots of a four-bar linkage.

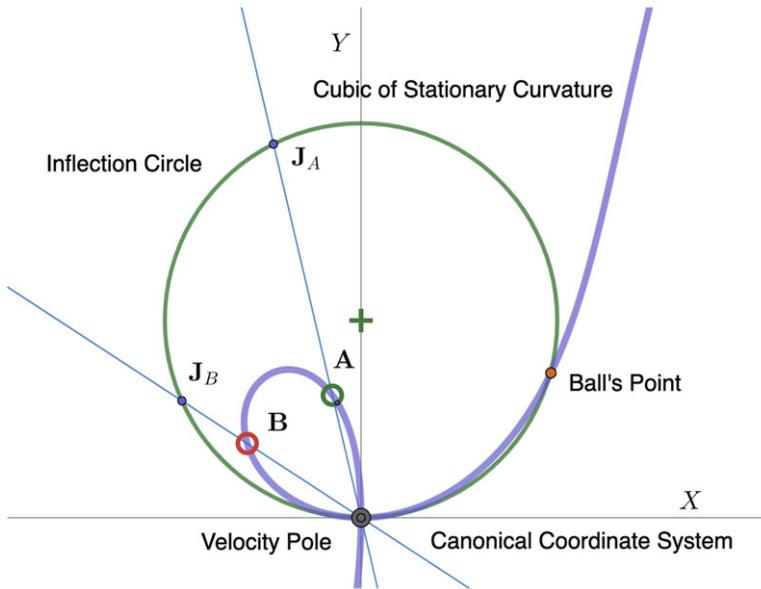

Figure 4. Points on the cubic of stationary curvature follow circular trajectories to the third order, and Ball's point follows a straight-line trajectory to the third order.

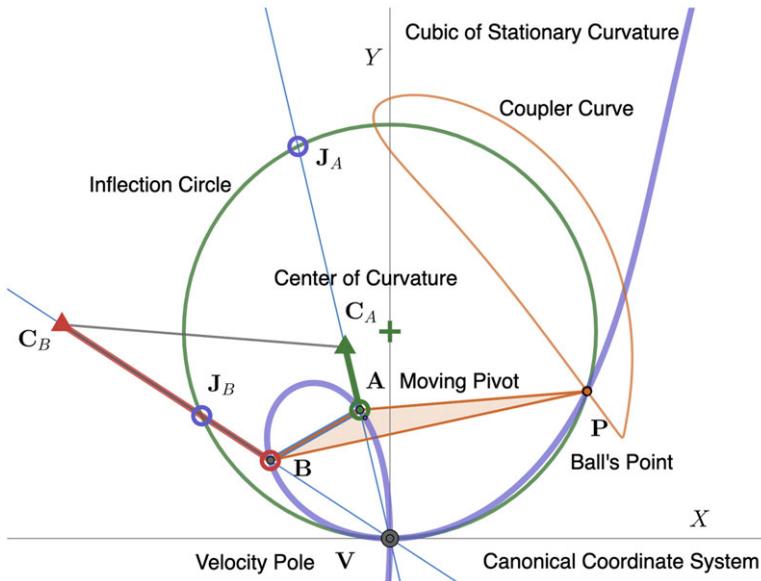

Figure 5. For a choice of moving pivots A and B , the centers of curvature C_A and C_B form the fixed pivots. The resulting linkage C_AABC_B guides Ball's point P along a flat-sided coupler curve.

The centers of curvature C_A and C_B for these trajectories are found using the Euler-Savary equation, which become the fixed pivots for bars connecting the moving body M to the ground frame F . The result is a four-bar linkage C_AABC_B with a coupler line AB that follows the movement of M to the third order.

Finally, we use *Ball's point* to obtain a flat-sided coupler curve that we use for the foot trajectory of our leg mechanism. See Fig. 5.

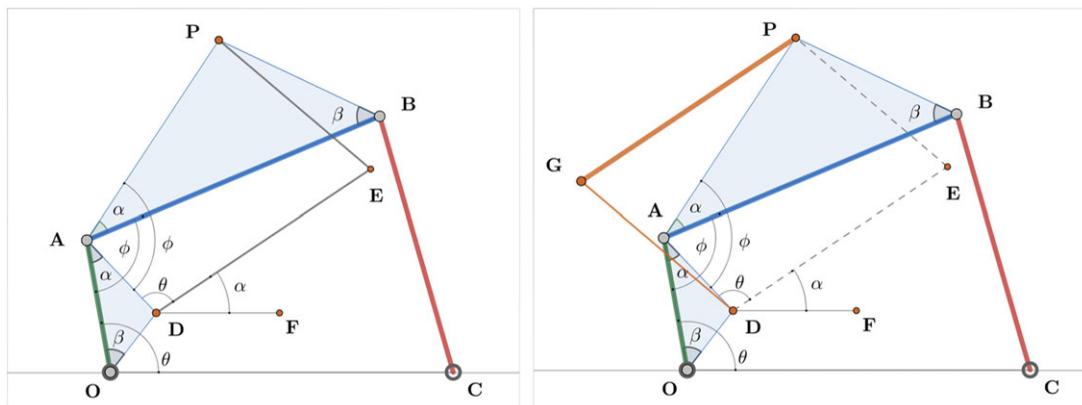

Figure 6. Left: Define the quadrilateral **DAPE** proportional to the original four-bar **OABC**. The angles α and β are constant and the coupler angle ϕ is the same for both quadrilaterals. The segment **DF** remains parallel to **OC**, and **DE** does not rotate. Right: Attach **DG** and **GP** to complete a parallelogram with **DE** and **EP** to obtain a non-rotating foot **PG** that follows the coupler curve traced by **P**.

3.2. Construct a translating link

Once a coupler curve is selected for the leg mechanism, two bars can be added to provide a translating link that will serve as the foot. The translating link is attached to the coupler point so that every point in the foot follows the same curve. The result is a six-bar leg mechanism with a translating foot. This construction follows Dijkstra [34].

Figure 6 shows a four-bar linkage **OABC** with the coupler point **P**. The resulting coupler triangle $\triangle ABP$ defines the angles $\alpha = \angle BAP$ and $\beta = \angle ABP$. Let the point **D** on the input link **OA** define a triangle $\triangle AOD$ similar to the coupler triangle. Then lengths of the segments **AP** and **AD** define a constant, k , given by,

$$k = \frac{|AP|}{|AB|} = \frac{|AD|}{|AO|}. \tag{20}$$

The addition of two links **DE** and **EP** with lengths,

$$|DE| = k |OC|, \quad \text{and} \quad |EP| = k |CB|, \tag{21}$$

yields a four-bar linkage **DAPE** that is proportional to the original linkage **OABC**, with equal coupler angles,

$$\phi = \angle OAB = \angle DAP. \tag{22}$$

As the coupler angle ϕ varies, the vertex angles of the two quadrilaterals remain the same throughout the movement. As a result, the segment **DE** maintains the angle α relative to **OC**, which shows that **DE** does not rotate as it moves.

In order to obtain a link that translates following the coupler curve of the **P**, we attach links **DG** and **GP** that complete the parallelogram with **DE** and **EP**, Fig. 6. Thus, the segment **PG** moves with **P** without rotating. The segments **DE** and **EP** are not physical links, so the leg mechanism becomes a six-bar linkage.

4. Leg system of the STAR walker

The design theory described in the previous section yields a six-bar linkage that guides a foot with a rectilinear, non-rotating, flat-sided trajectory. Two of these linkages are mounted on one side of the chassis of our STAR walker driven by a single actuated input crank to form a 10-bar leg system. See

Table I. The length (mm) of the links of the STAR walker leg mechanism.

Link	OA	AB	BC	CO	PA	PB	OD	AD	DG	GP
Length	24	49	54	70	54	45	22	26	58	76

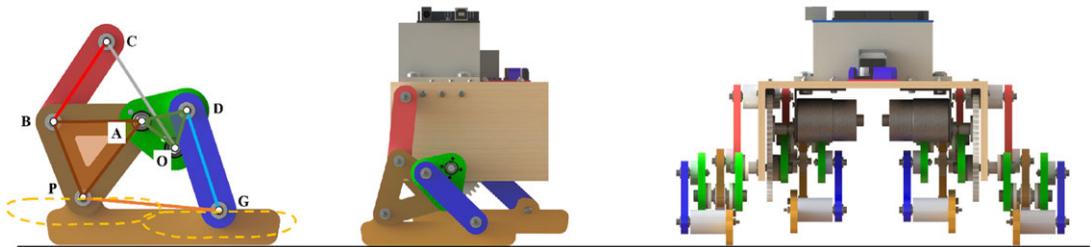

Figure 7. Left: The STAR walker six-bar leg mechanism. Links **DG** and **PG** are added to **OABC** to obtain a non-rotating foot. Center: Two leg mechanisms on one side form a leg system with one actuated input crank. Right: Front view shows the right and left leg systems.

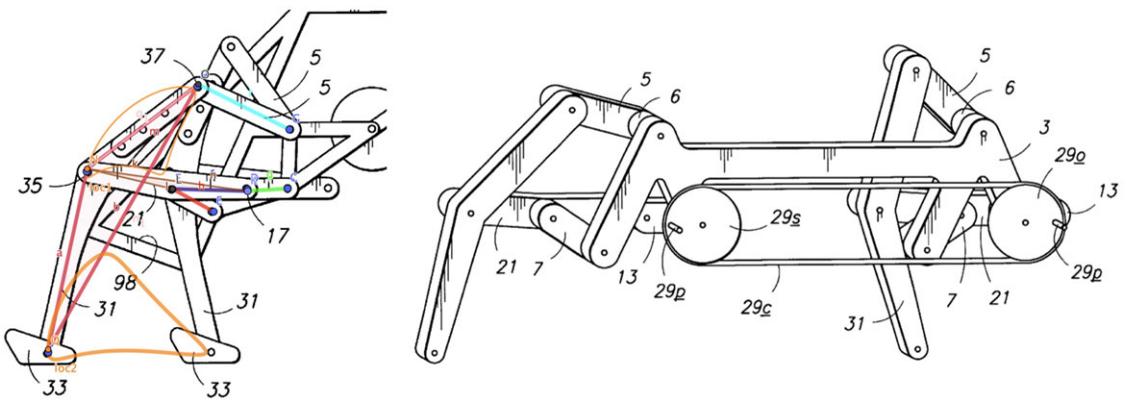

Figure 8. Left: The six-bar leg mechanism of the Klann Walking Device [35] generates a single point foot trajectory. Right: Two leg mechanisms with a single drive crank form a leg system on one side of the chassis. The leg provides single point contact and rotates during a step.

Fig. 7. The dimensions of the links are provided in Table I. The chassis of the walker is shaped like an inverted “U” with the vertical sides serving as the mounting structure for each leg system. The battery and electronics are mounted on the horizontal section of the chassis. It is useful to compare the STAR leg system to those of J. C. Klann’s Walking Device [35] and Chebyshev’s Plantigrade Walker [36].

4.1. Klann’s walking device

Like the STAR walker, the Klann Walking Device is also constructed using six-bar leg mechanisms. Two of these leg mechanisms and one side of the chassis form a leg system, which forms a 10-bar linkage with a single actuated input. See Fig. 8. The legs each provide single point of ground contact and the leg rotates around this point during a step. In contrast, the entire foot of the STAR walker maintains ground contact during a step.

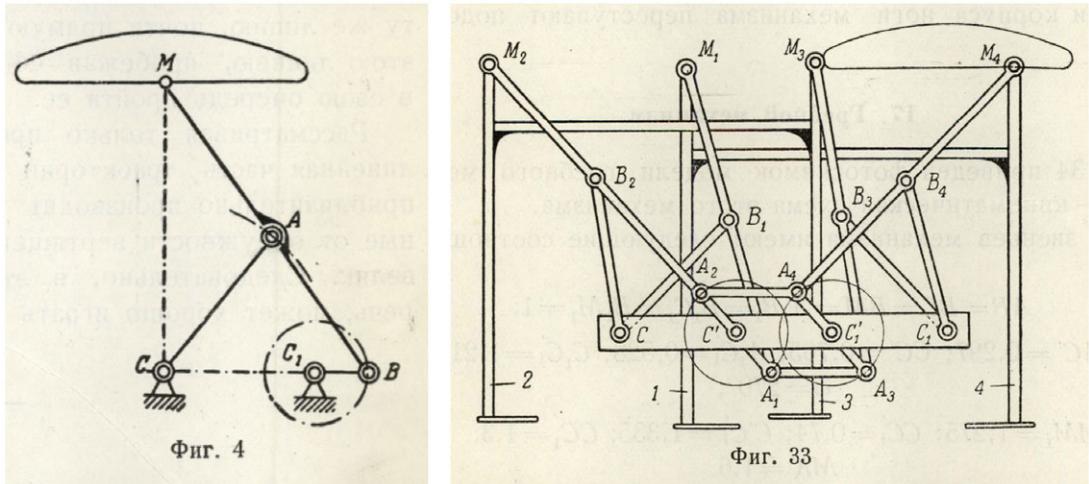

Figure 9. Left: Chebyshev's Lambda linkage is a four-bar linkage with a flat-sided coupler curve [37]. Right: Chebyshev's Plantigrade Walker has two rectilinear moving feet, one formed by items 2 and 3 and the other by items 1 and 4. The two feet follow the coupler curves of four Lambda linkages connected to a single crank [36] to provide non-rotating contact with the ground.

4.2. Chebyshev's plantigrade walker

Chebyshev's leg mechanism is a four-bar linkage that has the shape of the Greek letter *lambda* and is often called a *Lambda linkage* [37]. Chebyshev use this mechanism to drive two feet of a walking machine in rectilinear, non-rotating, fashion that is called *plantigrade*, which refers to walking on the soles of the foot. See Fig. 9. Chebyshev's Plantigrade Walker can be compared to one side of our STAR walker because it consists of two non-rotating feet driven by a single crank. In order to achieve this movement, Chebyshev connects four Lambda linkages, two for each foot. The result is a 14-bar leg system with a single input, which has more moving parts than our STAR walker.

5. STAR walker prototype

The components of the chassis of the STAR walker are laser cut from basswood. The links of the leg mechanism, the gears and spacers are 3D printed using PLA. See Fig. 10. Other hardware includes 3 mm joint bearings, hubs, shafts, screws and nuts.

The electronic schematic of the walker is shown in Fig. 11. The walker is driven by two 12V 56:1 DC motors (JGB37-520-C) with attached Hall-effect encoders (am-2816a) connected to an L298N mounted on an Arduino Mega. A BlueTooth (DX-BT24) interface allows control of the motor through a cellphone application. A 24V 3000 Amp Hour battery supplies power to the system.

This BlueTooth application provides a convenient graphical user interface to provide motion commands to the STAR walker. We set specific commands for forward, backward, left-turn, right-turn, self-rotation and stop, as well as speed increments. The result is the walker can be controlled wirelessly.

6. Walker control system

The controller for the drive motors of our walker uses proportional, differential and integral operations on the difference between the target speed and actual speed of the drive motors, to obtain rapid convergence to the target value, see Fig. 12. See Ogata [38] and Nise [39]. The speed of each motor is computed from the position information returned by the encoders. We use 50 ms cycle time to determine the rotational

Figure 10. The links, gears and spacers are fabricated by 3D printing PLA.

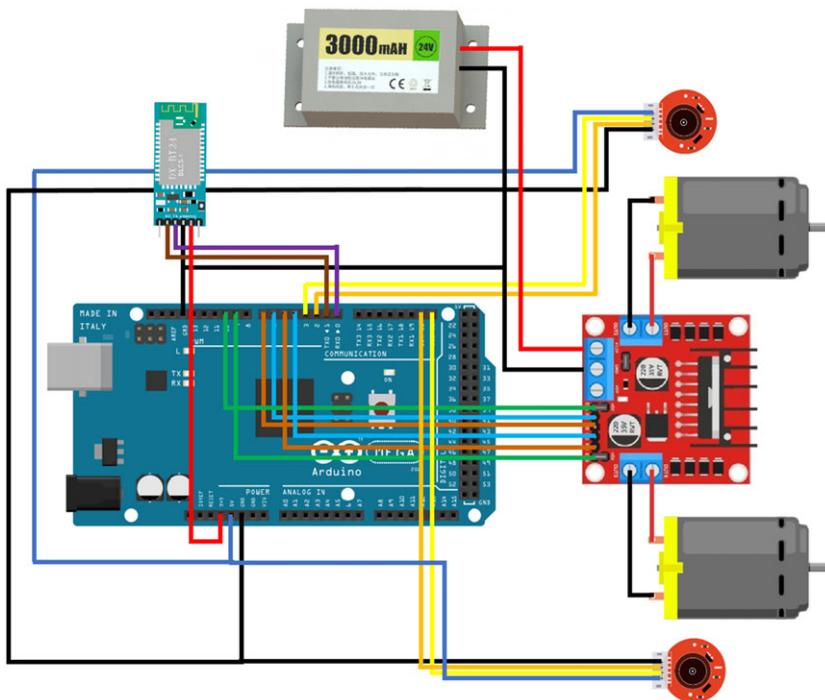

Figure 11. The Arduino Mega 2560 board collects control signals and encoder data, and sends a voltage command to the two DC motors.

speed of each motor. The coefficients, K_p , K_i and K_d , in the controller, are obtained by measuring the transient and steady-state performance of the walker. The values of these parameters were obtained experimentally by repeatedly tuning the response of the system.

The performance of the two walker motors under speed control is shown in Fig. 13. The four images represent the motor driving strategies of forward, backward, left-turn and right-turn motion, respectively.

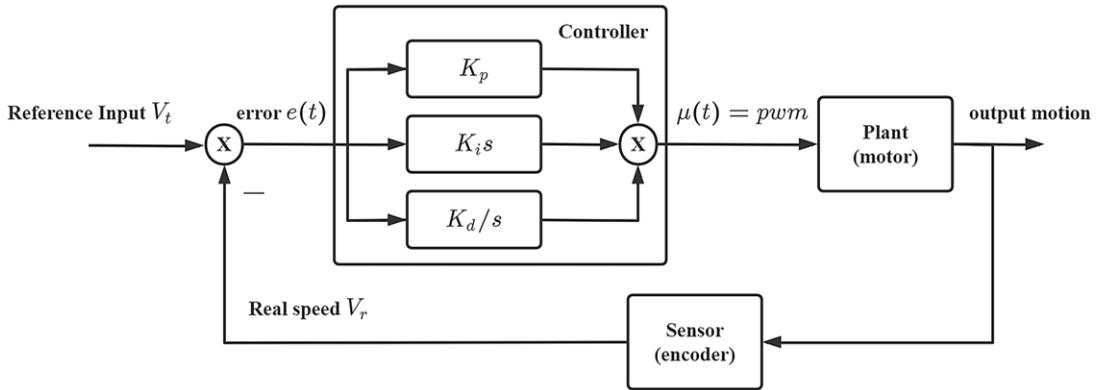

Figure 12. The speed PID controller block diagram.

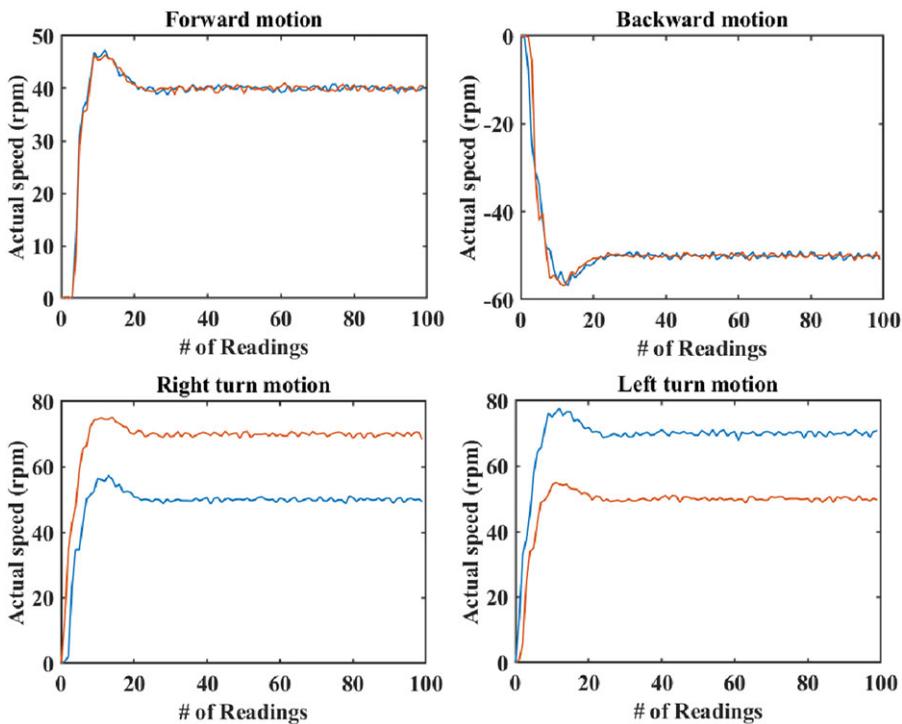

Figure 13. Motor speed under speed controller in (a) forward motion, (b) backward motion, (c) left-turn motion and (d) right-turn motion. Blue curve represents the right motor and red curve represents the left motor. All the data are collected without loads.

7. Results

The STAR walker is 190 mm long, 320 mm wide and 180 mm tall, and weighs 1.6 kg. Experiments were conducted to evaluate the performance of this walker for various movements. They consist of (a) an acceleration run over a 1 m track, (b) cornering around a one-quarter segment of a 1 m radius circle, (c) speed of a rotational movement about the z-axis of the walker and (d) evaluation of the vertical movement of the chassis.

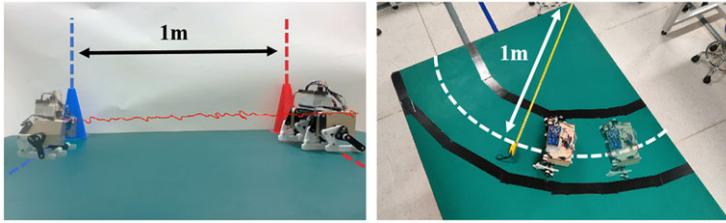

Figure 14. The STAR walker achieves a speed of 160 mm/s in a straight line, and 134 mm/s in a 1 m turn.

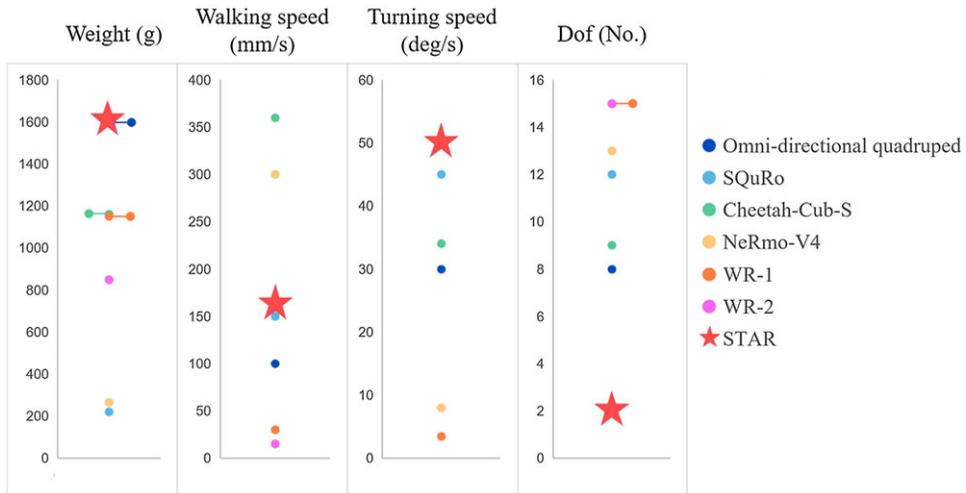

Figure 15. Comparison of weight, walking speed, turning speed and Dof among different quadruped walking robots.

The walker completed the acceleration run in 6.1 s, which is a speed of 160 mm/s (0.5 ft/s). The walker completed the quarter circle in 11.7 s, which corresponds to a speed of 134 mm/s (0.4 ft/s). This corresponds to a lateral acceleration in turning of 200 mm/s², which is approximately 0.02 g. See Fig. 14.

A comparison of the properties of our STAR walker with six other quadruped walking robots is shown in Fig. 15. The STAR walker includes a 350 g battery and two 170 g DC motors, therefore, it is the heaviest of these robots. However, STAR’s leg mechanisms provide a significant reduction in the number of DoF of the robot, which reduces the complexity of the robot’s control system and provides the fastest turning speed.

Comparing STAR to the Omni-directional quadruped introduced by Gu et al. [22], despite carrying a battery, STAR showcases similar weight and dimensions but outperforms in both walking and turning speeds. Likewise, when compared to Shi et al.’s [23] quadruped robot “SQuRo,” which is smaller and lighter, STAR exhibits superior walking and turning speeds. Although Cheetah-Cub-S, introduced by Weinmeister et al. [24], reports a faster walking speed, STAR excels in turning speed. A similar pattern emerges when comparing STAR to NeRmo-V4 by Lucas et al. [25]. Additionally, when compared to Ishii’s animaroid robots, WR-1 [26] and WR-2 [27], which have many DoF and relatively small sizes, STAR has an advantage in control complexity (DoF) while maintaining faster walking and turning speeds.

In-place rotation was achieved by driving both legs to move in opposite directions and was measured using an IMU (JY60, WitMotion, Shenzhen, Guangdong, China), Fig. 16. The time for a full turn was obtained as 7.2 s, which is an angular velocity of 50°/s. The roll and pitch angles of the robot during a forward walking movement were measured using IMU data, see Fig. 17. The STAR walker shows a

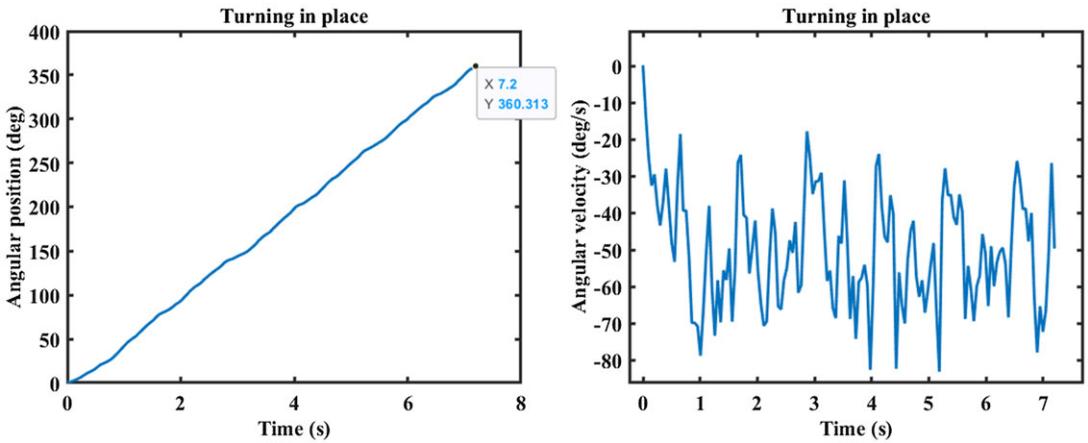

Figure 16. The STAR walker can rotate in place at a speed of 50°/s.

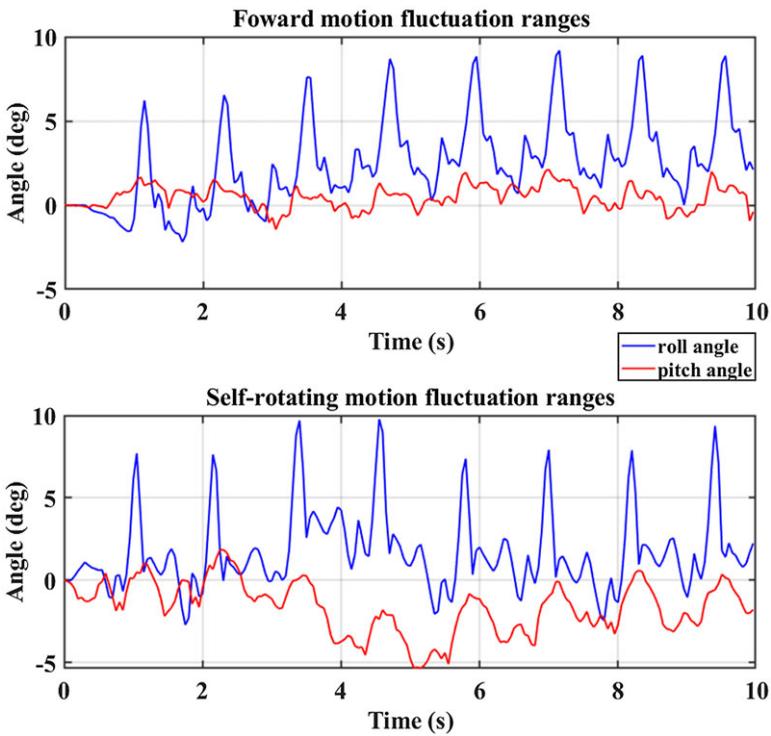

Figure 17. Roll and pitch angle of forward motion and self-rotating motion.

range of fluctuation at 10° for roll angle and 3° for pitch angle during forward motion, and 11° and 6° during a turning motion. In comparison, the Omni-directional quadruped [22], reports a fluctuation of 4° for roll angle and 6° for pitch angle during forward motion, and 13° and 10° for pitch angle during rotating motion. This indicates that the STAR walker maintains a higher degree of stability during its walking motions.

The vertical movement of the walker chassis was evaluated by tracing the trajectory of the chassis top right corner to determine the maximum variation. See Fig. 18 which shows this trajectory as well as the trajectory of the same point in a SolidWorks simulation. The peak to peak maximum of this vertical

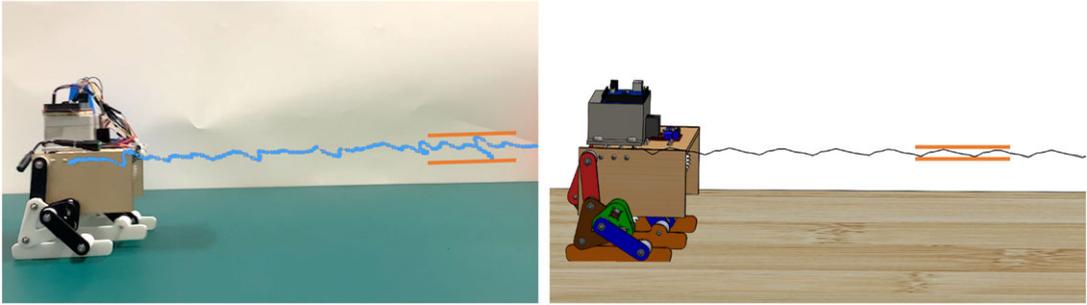

Figure 18. Comparison of the vertical chassis movement of the SolidWorks simulation to the performance of the STAR walker. The prototype shows a vertical movement that is three times that of the simulation.

movement for the prototype was measured to be 30 mm. The variation of 15 mm is 8.1% of the 185 mm height of STAR walker. This is three times the 11 mm peak-to-peak vertical movement measured in the SolidWorks simulation. The difference appears to arise from manufacturing tolerances in the leg mechanism. During motion, the walker's center of mass moves within the support polygon provided by the rectilinear, non-rotating, moving feet. This combines with manufacturing tolerances in the leg systems to cause variation in the orientation of the chassis that is not seen in the simulation. We will address this in future research.

8. Conclusion

In this paper, we have presented the design and control of a novel four-legged robot walker (the STAR walker) based on a one-degree-of-freedom six-bar leg mechanism. The STAR walker is statically stable and driven by only two actuators, one for each side, providing rectilinear movement of the foot on a flat surface. The goal of our design is to reduce the complexity and weight of the robot while maintaining effective locomotion capabilities.

Our results show that the robot walker achieved a speed of 162 mm/s in a straight line, 134 mm/s in cornering (0.02 g lateral acceleration), and was able to rotate about its axis at 50°/s. During these movements, the vertical displacement of the chassis was measured to be 30 mm.

For future applications, compared to other walking robots of similar size, the STAR walker has the fewer degrees of freedom and larger load capacity. The reduced number of actuators reduces energy consumption, which makes the STAR walker suitable for long-duration detection and transportation tasks. The fewer number of actuators also leads to easier control and lower manufacturing costs, making it possible for STAR to be used as a module in large-scale robot clusters. This makes it ideal for logistics warehousing, environmental monitoring and rescue tasks.

Future work will focus on improvement to the design and control of the robot walker to enhance its performance over uneven terrain, and obstacle negotiation. This research opens new opportunities for developing advanced robot walkers with improved mobility and versatility for various real-world applications.

Author contributions. Ken Nguyen and J. M. McCarthy originated the design for the leg mechanism of a two-legged wheeled walker. Chenhao Liu and J. M. McCarthy further developed this design. Chenhao Liu and Jiaji Li achieved the four-legged version. All four authors contributed to writing this article.

Financial support. This research received no specific grant from any funding agency, commercial or not-for-profit sectors.

Competing interests. The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential Competing interest.

Ethical approval. Our study does not include experimentation with vertebrates.
